Abstract
Children less than 18 years of age account for an estimated 2%–5% of reported severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) cases globally. Lower prevalence of coronavirus disease 2019 (COVID-19) among children, in addition to higher numbers of mild and asymptomatic cases, continues to provide challenges in determining appropriate prevention and treatment courses. Here, we summarize the current evidence on the transmission, clinical presentation, complications and risk factors in regard to SARS-CoV-2 in children, and highlight crucial gaps in knowledge going forward. Based on current evidence, children are rarely the primary source of secondary transmission in the household or in child care and school settings and are more likely to contract the virus from an adult household member. Higher transmission rates are observed in older children (10–19 years old) compared with younger children (<10 years old). While increasing incidence of COVID-19 in neonates raises the suspicion of vertical transmission, it is unlikely that breast milk is a vehicle for transmission from mother to infant. The vast majority of clinical cases of COVID-19 in children are mild, but there are rare cases that have developed complications such as multisystem inflammatory syndrome in children, which often presents with severe cardiac symptoms requiring intensive care. Childhood obesity is associated with a higher risk of infection and a more severe clinical presentation. Although immediate mortality rates among children are low, long term respiratory, and developmental implications of the disease remain unknown in this young and vulnerable population.

epidemiology, pulmonology (general), social dimensions of pulmonary medicine

1 | INTRODUCTION

Children less than 18 years of age account for an estimated 1.7% of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) clinical infections in the United States,1 with global estimates ranging from 2.0% to 4.8%.2 The low prevalence of pediatric cases has made it difficult to draw conclusive statements about many aspects of the virus in this population, but the reported case numbers are likely an underestimation of the true pediatric case load, as many cases in children are mild or asymptomatic.3 Initial observations report that
the clinical course is generally milder and outcomes are better in children.\(^5\) Also, as the pandemic progresses, clinicians report an increasing number of cases of multisystem inflammatory syndrome in children (MIS-C), a severe inflammatory syndrome following coronavirus disease 2019 (COVID-19) exposure or infection. Though rare, this syndrome has the potential to cause devastating outcomes in children and as the pandemic continues cases of MIS-C are likely to increase. These findings have underscored the limitations of current knowledge regarding COVID-19 in children and have raised questions about the implications for long-term respiratory and developmental prognosis. We seek to comprehensively examine what is currently known and what knowledge we still lack about transmission, clinical presentation, complications, and risk factors as they pertain to SARS-CoV-2 infection in the pediatric population. In so doing, we seek to link these four areas of concentration, providing the reader with an overview of the risk of COVID-19 to children.

2 | METHODS

A literature review was carried out to identify both published and non-peer-reviewed pre-print original studies and review papers from January to December 2020, relating to the transmission, clinical presentation, complications, and risk factors of COVID-19 in the pediatric population. Searches were conducted in PubMed, MedRxiv, and the Johns Hopkins "COVID-19, Maternal and Child Health, Nutrition" repository. Case studies and papers containing duplicate analysis of data already included in our review were not selected.

2.1 | Transmission

According to the WHO,\(^6\) SARS-CoV-2 is transmitted directly and indirectly through the respiratory secretions of those infected. Several studies have also looked at the prevalence and implications of fecal viral shedding in the pediatric population and the implications for transmission.\(^7\) Based on a systematic review of contact tracing programs and population studies, the susceptibility of children to COVID-19 was lower than adults, although the role that they played in transmission was not conclusive.\(^8\)

The prominence of mild and asymptomatic illness in pediatric patients has created concern that the true prevalence of disease in this age group has been underreported.\(^4,5\) Population-based seroprevalence studies have had conflicting results.\(^9,10\) The seroprevalence of antibodies in children was consistent with that of adults in the same area in the UK,\(^9\) implying that children and adults are equally susceptible to the virus, however, in Italy seroprevalence increased with age.\(^11\) Similar to reports in the adult population, racial, and socioeconomic disparities have also been noted among pediatric populations with studies noting higher rates of transmission among racial and/or ethnic minority groups\(^12\) with more severe health outcomes.\(^13\)

2.1.1 | Household transmission

Table 1 presents transmission sources as reported in several pediatric studies. Available data indicate that SARS-CoV-2-positive adults living in the household are the primary source of infection for children. It should be noted that shelter-in-place orders decreased outdoor activities in most countries and likely led to the increase of viral spread within households.\(^14\) In an investigation of 110 cases stemming from 11 infection clusters in Japan, close contact in an indoor setting contributed to all 11 clusters.\(^15\) In South Korea, household cases were the primary source of infection until mid-March, 2020, when imported cases became the most prevalent.\(^4\) In the UK, a population-based seroprevalence study of children reported that neither age nor gender had any association with positive results, but contact with a household member with confirmed COVID-19 was a significant predictor for seropositivity.\(^9\)

Although children are usually infected by SARS-CoV-2-positive adults living in the household, several studies have shown that the overall risk of contagion to children is lower than that of other adults residing in the same household.\(^14,16\) In a meta-analysis looking at secondary attack rates (SAR) in the household setting (n = 54 studies),\(^14\) the overall estimated SAR for household contacts was 16.6%, while that of close contacts was just 4.8%. Spouses of infected individuals were at greater risk than other household members (37.8% vs. 17.8%), whereas the rate of secondary household transmission to children was significantly lower than adults (16.8% vs. 23.3%).\(^14\)

A child’s age may also affect the risk of transmission. In South Korea, analysis of data for 59,000 contacts of 5700 index cases found that a total of 11.8% of household contacts tested positive for COVID-19.\(^24\) When further stratified by age, the infection rate was 18.6% for index cases aged 10 to 19 years, and 5.3% for ages 0 to 9 years.\(^24\) Consistently, in a study of Swiss students, the seroprevalence of SARS-CoV-2 antibodies decreased with age.\(^10\)

2.1.2 | Maternal–fetal and perinatal transmission

Vertical transmission was demonstrated with SARS-CoV-1, and the same risk theoretically exists for SARS-CoV-2, as the viral receptor (angiotensin-converting enzyme 2 [ACE-2]) is widely expressed in the placenta.\(^25\) Although a systematic review of 18 studies (n = 157 mothers and 160 neonates) found no evidence of vertical transmission,\(^56\) the growing number of confirmed neonatal cases of COVID-19 infection has reinforced the suspicion that SARS-CoV-2 is similarly capable of crossing the placenta to infect fetal lungs. A recent study identified three neonates delivered from COVID-positive mothers with pneumonia on chest radiography (CXR) obtained at birth and nasopharyngeal (NP) swabs positive for SARS-CoV-2 on Days 2 and 4 of life and negative on Day 6.\(^7\) One of these patients was born at 31 weeks of gestation via cesarean delivery due to fetal distress and required resuscitation. Although vertical transmission was not found in several other neonates born to COVID-19 infected mothers, it is critical to note that most of such data have been limited by extremely small sample size.
Based on the earliest 13 case series/series (49 milk samples from 22 women combined, only one sample contained virus, while SARS-CoV-2 was found in 10/11 (90%) infants who were tested. As positive mothers following delivery (Day 0), the first mother's samples were all negative for SARS-CoV-2 RNA but milk samples from Day 12 and 13 postdelivery were positive for the second mother. 

As of July 31, 52 (33 confirmed) SARS-CoV-2 cases had occurred in 29466 (4.3%) child care facilities in Rhode Island.27 Twenty of these 29/666 (4.3%) child care facilities only reported a single case, with no evidence of secondary transmission. Additional studies identified 77 infants of COVID-19-positive mothers as having symptoms following exposure to SARS-CoV-2. 

As of July 31, 52 (33 confirmed) SARS-CoV-2 cases had occurred in 29466 (4.3%) child care facilities in Rhode Island.27 Twenty of these 29/666 (4.3%) child care facilities only reported a single case, with no evidence of secondary transmission. Additional studies identified 77 infants of COVID-19-positive mothers as having symptoms following exposure to SARS-CoV-2.

Abbreviation: SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

*A householder member included, author did not specify whether adult or sibling was the source.

*Both household and close contacts included in this data point.

As of July 31, 52 (33 confirmed) SARS-CoV-2 cases had occurred in 29466 (4.3%) child care facilities in Rhode Island.27 Twenty of these 29/666 (4.3%) child care facilities only reported a single case, with no evidence of secondary transmission. Additional studies identified 77 infants of COVID-19-positive mothers as having symptoms following exposure to SARS-CoV-2.
transmission, while possible secondary transmission occurred in four centers, accounting for 17 cases. Contact tracing and testing data for child care facilities in Salt Lake City, Utah, in April July, 2020, reported 31 confirmed cases of COVID-19 between three facilities, 42% (13/31) of which occurred in children. Asymptomatic transmission from children to adult contacts was confirmed in two cases. Index cases for all three facilities were determined to be adult staff members.

2.2.1 | School opening and transmission

Table 2 provides data from studies analyzing secondary transmission of SARS-CoV-2 in the school setting. In South Korea, children were not the primary source of transmission within schools, as secondary cases were all a result of contact with an infected staff member. In England, staff had higher incidence rates than students and accounted for most cases linked to outbreaks. In Ireland, no secondary transmission of COVID-19 was reported in a follow-up of 1025 exposed school contacts. These exposures included activities such as music lessons and choir practice, both of which are assumed to be high-risk activities for transmission. Of 18 cases of secondary transmission in Australia, five cases occurred in three schools and the other 13 occurred in a single early childhood education center where the cluster outbreak was traced to a single adult staff member. The overall child-to-child SAR was 0.3% (2/649) and the child to staff SAR was 1.0% (1/103), while the staff-to-staff SAR was 4.4% (7/160) and the staff-to-child SAR was 1.5% (8/536). In Switzerland, researchers randomly analyzed seroprevalence among 2585 students (6-16 years old) in 55 schools and found that at least one seropositive case was reported in 36/55 schools with no evidence of clustered outbreaks or secondary transmission. In Hong Kong, only 5 of 20 cases in children (5-17 years old) were associated with two clustered school outbreaks. Only six of these cases contributed to the transmission of SARS-CoV-2 to an additional 11 students. No additional secondary transmission was reported despite extensive screening and monitoring of more than 2300 close school contacts. Authors of both papers acknowledged the contribution of infection-control measures, such as social distancing and masking, to the low transmission rates. Child-to-child transmission within the school

Abbreviations: ECEC, early childhood education and care centers; SAR, secondary attack rate; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

*aAuthor did not specify the type of schools at which the adult staff members worked. Also, no clarification was made about whether more than one of the six cases was present in a single school.

b1025 contacts were monitored, symptomatic individuals were referred for testing, but exact numbers are unknown ± ECEC: early childhood education and care centers. Account for daycare, preschool and after-school care programs.
setting was uncommon and not the primary source of SARS-CoV-2 infection in children.44

Ten days after schools reopened in Jerusalem in May, 2020, two separate cases of COVID-19 in the same high-school led to the infection of almost 260 people.47 Within the school community, 153 students and 25 staff members were infected. Overly crowded classrooms without appropriate social distancing and the suspension of mask-wearing for several days in response to a heat wave likely contributed to the outbreak.47

School infections peaked in Victoria, Australia, when community transmission was high, but transmission among children was not school driven.48 Controlling community incidence is likely an effective means of controlling transmission within the educational setting.40 In Sweden and Finland, the cumulative incidence rates of COVID-19 among school-age children were similar across both countries despite Sweden’s decision not to close childcare facilities or primary schools. Health officials in Sweden concluded that school closures did not significantly impact the overall prevalence of COVID-19 among 1-19 year-olds.48 Daycare, primary, or secondary school teachers were not at increased risk for SARS-CoV-2 infection.49

Children do not appear to be the primary drivers of SARS-CoV-2 transmission in the home or school settings and often present with mild or asymptomatic cases when infected.

3 CLINICAL PRESENTATION IN CHILDREN

Table 3 summarizes 12 studies reporting clinical data of children with diagnosed or suspected COVID-19.5 The heterogeneity in study participant selection criteria must be noted among these studies, which may have affected both clinical presentation and severity of the cases reported.

In a systematic review of literature regarding the clinical presentation of COVID-19 in children, the most commonly reported symptoms were fever and cough.5 In a cohort study involving 651 pediatric cases in the UK, fever and a runny nose were more common in younger children, while vomiting, abdominal pain, headache and a sore throat showed an increasing trend with age.50 Older children were more likely to present with respiratory distress than infants (44% vs. 7%).57 Less common symptoms include seizures,5,50,53 and loss of taste and smell.5,17

A study of 2143 (731 laboratory-confirmed) pediatric cases reported to the Chinese Center for Disease Control and Prevention found that 94.1% of cases could be classified as asymptomatic, mild, or moderate.5 The mild category (50.9%) included symptoms such as fever, fatigue, myalgia, cough, sore throat, runny nose, and sneezing.5 In Turkey, of 220 positive pediatric cases, 145 (70.5%) were classified as asymptomatic (25.5%) or mild (45%).19 In South Korea, 22% of COVID-19-positive study participants remained asymptomatic throughout a 3-week monitoring period.6 A systematic review of studies (n = 4300 confirmed pediatric cases) reported that 18.9% of children were asymptomatic.55 The majority of studies reported a mortality rate of less than 2% (Table 3).

There is a significant difference in the median age between studies, with the lowest being 2.3 years old16 and the highest 13 years.53 Infants (aged < 1 year) account for between 30% and 40% of participants in half of the studies (Table 3). The high proportion of infants could be influenced by a tendency for parents to seek medical attention for this age group and an increased likelihood that physicians will admit them to hospitals.16 A multivariate analysis reported an association between neonatal period (<1 month of age) and ICU admission (odd ratio 5.06).18

Several studies noted that COVID-19 positive patients had elevated blood markers indicative of inflammation.17,19,50,51,53 One study reported that 38.8% (47/121) of participants had high concentrations of the inflammatory marker C-reactive protein (CRP).16 Moreover, children with more serious symptoms were found to have significantly higher CRP levels than those with a milder presentation.57 In Turkey, lymphopenia was the most common abnormal lab value found amongst participants (13.5%; 85/220).19

While COVID-19 in children can present with a variety of symptoms, pediatric cases are most often mild or asymptomatic. In rare cases, children can develop severe complications following infection.

4 COMPLICATIONS IN CHILDREN

4.1 Multisystem inflammatory syndrome in children (MIS-C)

Starting in late April 2020, a hyperinflammatory syndrome likely related to COVID-19 has been reported in growing numbers of children.54,55 This syndrome has been named multisystem inflammatory syndrome in children (MIS-C) and its clinical presentation has many similarities to Kawasaki Disease (KD)58 and Toxic Shock Syndrome (TSS), particularly the elevation of multiple inflammatory markers with severe cardiac involvement.50,56,59-62

In the UK, MIS-C is referred to as pediatric inflammatory multisystem syndrome temporarily associated with SARS-CoV-2 (PIMS-TS).63

Table 4 summarizes 14 studies looking at patients with potential or diagnosed cases of MIS-C. The information is presented in table format for ease of viewing, but not necessarily for comparison among studies as they vary greatly in size and scope. Patient selection also varies among studies, with earlier studies responding to an unusual increase in KD cases in the pediatric population and selecting study cases from those with a definitive KD diagnosis. Later, as the medical and scientific community became aware of MIS-C as a distinct condition, more formal diagnostic characteristics were sought.64 Since then, the WHO,65 the Centers for Disease Control (CDC)66 in the United States, and the Royal College of Paediatrics and Child Health63 in the UK have all provided separate case definitions.

4.2 Clinical presentation of MIS-C

Fever, gastrointestinal complaints, rash, and conjunctivitis have been reported as the most prevalent symptoms MIS-C (Table 4), although a combination of these symptoms must be present in order for patients to meet the case definition for MIS-C or PIMS-TS.64 Due to the overlapping clinical features of MIS-C and KD, RT-PCR and antibody testing are needed to confirm MIS-C.58,60,67

4.3 MIS-C and SARS-CoV-2 testing results

Although the causality of MIS-C is currently inconclusive, several studies have noted an increase in cases 4–6 weeks following a spike in COVID-19 cases within a population.50,62,69,72,73 In several studies, patients found to be negative for SARS-CoV-2 by RT-PCR were positive for SARS-CoV-2 antibodies.56,59 SARS-CoV-2 RT-PCR was positive in 52% of cases, while SARS-CoV-2 antibodies were found in almost 71% of cases across all available studies (Table 4). Riphagen et al.67 reported that all eight cases in their study tested negative for SARS-CoV-2 by RT-PCR, but no mention of antibody testing was noted.67 Serum samples from 29 pediatric patients, showed that cases classified as MIS-C had higher IgG antibody titers than their non-MIS-C counterparts,74 which is consistent with the delayed onset of MIS-C cases following COVID-19 exposure and/or infection.74 UK patients with MIS-C who were antibody-positive were younger (median age 10.0 years vs. 12.4 years) and more likely to be of non-White ethnicity than those who were positive by RT-PCR,50 suggesting that more testing is needed in younger and minority children. Conjunctivitis (71% vs. 16%) and abdominal pain (95% vs. 44%) were more common in patients positive for SARS-CoV-2 antibodies, whereas those who were diagnosed by RT-PCR testing were more likely to present with shortness of breath (52% vs. 14%).50

4.4 MIS-C and patient characteristics

Due to the severity of the clinical presentation, children with MIS-C often require ICU-level care, especially to manage cardiac complications. In one study, children with MIS-C were five times more likely to be admitted to the ICU,50 while another study reported that 14 of 15 MIS-C patients were admitted to the ICU within 24 h of hospital admission.59 In Latin America, lower socioeconomic status was found to have a significant association with MIS-C diagnosis and the need for mechanical ventilation.72 Different from adults, there are conflicting data regarding comorbidities that place children at higher risk for COVID-19 complications, and several studies reported that the majority of their pediatric subjects did not have any significant past medical history.22,56,59,62,67 A possible exception to these findings was reported where five of six patients diagnosed with MIS-C had a pre-existing medical condition, four of whom were immunocompromised.70

Note: Cardiac symptoms ex. abnormal EKG, elevated serum troponin and/or BNP, coronary artery abnormalities, arrhythmias, ventricular dysfunction, myocarditis; features of Kawasaki Disease: includes symptoms such as erythema and cracking of lips, strawberry tongue, rash, conjunctivitis, swollen hands and feet, myocarditis, lymphadenopathy (McCrindle et al.58); and features of shock: hypotension, tachycardia.

Abbreviations: Ab, antibodies; Gl, gastrointestinal complaints ex. diarrhea, vomiting, abdominal pain; KD, Kawasaki Disease; LRI, lower respiratory tract infection ex. pneumonia, bronchitis; Pna, pneumonia; Resp, respiratory complaints ex. cough, shortness of breath; RT-PCR, reverse transcription polymerase chain reaction; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2; URI, upper respiratory tract infection ex. rhinitis, pharyngitis, tonsillitis, otitis.

*aLargest racial or ethnic group(s) reported in each study. Language used is that of the authors. Swann et al.50 reported that children of black ethnicity were over represented in their study population compared to the general population (10% vs. 4.7%). No other authors offered context for racial/ethnic data. It is also assumed that neither race nor ethnicity are mutually exclusive.

*b85% of participant’s parents reported being of Chilean descent.

*Value includes participants who tested positive for SARS-CoV-2 antibodies.
Though pediatric mortality rates are low, even among those diagnosed with MIS-C, there continues to be significant concern regarding which, if any, comorbidities place children at increased risk for COVID-19 infection.

5 | COMORBIDITIES AND SEVERITY

Obesity, chronic respiratory diseases (particularly asthma), and a compromised or suppressed immune system are the most common underlying medical conditions that have been cited. Table 5 summarizes 12 studies that have included comorbidity data.

5.1 | Obesity

Obesity was the most common comorbidity among hospitalized COVID-positive children, with a significant association between obesity and severe cases requiring mechanical ventilation in children 2 years and older.17 A retrospective study from Wuhan, China, reported that an elevated body mass index (BMI) was correlated with an increased mortality risk in COVID-19 patients aged 14 45 years.79 In another study, 30% (14/46) of admitted pediatric patients testing positive for COVID-19 were obese, but no correlation was noted between obesity and ICU admissions.79 Finally, an analysis of nationwide data from pediatric cases in Mexico reported that obese children were 33% more likely to have a SARS-CoV-2 infection.77

The effect of the COVID-19 lockdown policies on weight gain in children is also of concern. A cross-sectional survey of 584 households in the United States reported that families are buying more nonperishable and highly processed foods, and a third of families also reported an increase in their consumption of snack foods and desserts.80 In a longitudinal study of 41 obese youth in Italy, the intake of food items linked to obesity, such as potato chips, red meat, and sugary drinks had increased significantly while time spent in sports activities had decreased during the first 3 weeks of the national lockdown.81 The wide disruption in the diet and activities of children due to lockdown policies has the potential to worsen the ongoing obesity epidemic, which in turn places children at greater risk for COVID-19 infection.82

5.2 | Chronic respiratory disease

As COVID-19 is primarily a respiratory illness, asthma and other respiratory conditions were initially thought to place children at higher risk for more severe symptoms. However, there are conflicting data about the risk of COVID-19 in children with chronic respiratory illnesses. A study looking exclusively at COVID-19 patients receiving ICU care53 did not show a significantly higher proportion of asthmatics than studies at all hospitalized children.69 Underlying respiratory conditions were present in only 4.3% (21/491) of those requiring general care, while 10.4% (12/115) of those requiring ICU care reported the same.50 Not one of 67 studies included in a systemic review reported asthma as a comorbidity or risk factor for children and COVID-19.83 In a study of COVID-19 pediatric cases in Mexico, asthma was reported in 3.8% (806) of all cases, but was not associated with increased severity of infection; those reporting asthma were not more likely to develop pneumonia, nor were they at higher risk for hospitalization.77

Surprisingly, an Italian study reported a much lower prevalence of asthma in their pediatric COVID-19 cohort than in the general population (2% vs. 11%).78 Researchers postulated the potential for asthma to act as a protectant due to adaptation in the immune response of pediatric asthmatics.78 Behavioral factors may also have contributed to the lower prevalence of pediatric asthmatics among COVID cohorts. Several studies reporting a significant decrease in pediatric asthma-related visits to emergency departments and an increased utilization of telehealth raise the possibility that parents with vulnerable children are being proactive in protecting them against unnecessary exposure to COVID-19.84,85

5.3 | Immune system compromise

Comorbidities involving immunocompromise include organ transplants, malignancies, and aplastic anemia (Table 5). Notably, some studies used immunocompromised and immunodeficient interchangeably.18 Individuals using immunosuppressants and those receiving chemotherapy and/or radiation are considered to be immunosuppressed.

Available data concerning the risk of COVID-19 in patients with immunodeficiencies and/or immunosuppression are contradictory. In a study of 91 pediatric cases in South Korea, none reported an existing immunodeficiency.4 These 91 cases account for 76.5% of all pediatric cases in the country, excluding a cluster outbreak within a religious community.4 In Spain, 8/53 (15%) of the total pediatric COVID-19 cases for a single month were immunocompromised.86 Only 8.1% (53/599) of pediatric cases in the UK reported use of immunosuppressants before being hospitalized for COVID-19.60 There was no association between immunosuppressant use and critical care admission.60 In Mexico, immunodeficiencies were reported in 3.8% (808) of all cases and were associated with a four-fold increase of COVID-19 pneumonia and eight-fold increase in the risk of hospital admission.77

5.4 | Viral co-infections

In a retrospective study from China, researchers reported that 47.1% (16/34) of COVID-19-positive pediatric patients were infected with additional respiratory pathogens, including Mycoplasma pneumoniae, influenza type A and B, and respiratory syncytial virus (RSV).57 In another study from China, 10 pediatric patients were extensively evaluated and all were negative for both common viruses (RSV, influenza, etc.), SARS-CoV, and MERS-CoV.7 In Italy, 5.9% (10/168) of

Abbreviations: BMI, body mass index; SARS-CoV-2, severe acute respiratory syndrome coronavirus 2.

*Obesity is defined as BMI (or sex and weight for length percentiles for patients younger than 2) at or above the 95th percentile for age.

bSolid organ transplant, hematologic malignancies, solid tumors, hematopoietic stem cell transplant recipient, aplastic anemia.

*Study explicitly states or demonstrates the inclusion of asthma in data point for chronic respiratory illness.
study participants had co-infections,\textsuperscript{16} while in Perú, \textit{M. pneumoniae} was found in 10\% (9/91) of participants.\textsuperscript{53} In Latin America, 3.4\% (14/409) of participants tested positive for a viral co-infection, although no significant association was found between co-infections and ICU admission or mechanical respiratory support.\textsuperscript{72} In contrast, in Europe, 5\% (29/582) of participants tested positive for a viral co-infection and patients with one or more viral co-infections were more likely to have signs or symptoms of upper or lower respiratory tract infection at presentation.\textsuperscript{18} Individuals with viral co-infection were also significantly more likely to require ICU admission, respiratory support, and vasoactive medications.\textsuperscript{18}

Overall, there is limited data regarding the presence of viral coinfections within the COVID-19-positive pediatric population. There is also limited evidence regarding the influence of these co-infections in either increasing a patient’s susceptibility to COVID-19 or in contributing to a more severe course of disease. With expected peaks of additional respiratory pathogens like influenza and respiratory syncytial virus during the winter season, we will likely experience the true impact of multiviral respiratory infections in terms of both incidence and clinical severity.

6 | SUMMARY

Preliminary findings are generally optimistic respecting incidence and severity of SARS-CoV-2 infection in the pediatric population. Children do not appear to be the primary source of transmission within either the household or school environments, and are most likely to contract the virus from an adult household member. As SARS-CoV-2 transmission through breastmilk is unlikely, the current recommendation for mothers with suspected or confirmed COVID-19 is to initiate or continue breastfeeding while following guidance on hygiene and mask use. Findings on perinatal transmission are inconclusive, and further studies of pregnancy outcomes and post-natal fetal development of infants of COVID-positive women are warranted.

The large proportion of cases studied thus far have shown that children often have a mild or asymptomatic presentation. While rare, there are hundreds of children in the United States that have met case definition for MIS-C.\textsuperscript{69} Despite the potential for catastrophic outcome, the WHO, the CDC, and the Royal College of Paediatrics and Child Health have all provided formal diagnostic criteria for MIS-C,\textsuperscript{65,66} allowing for faster treatment and an overall positive prognosis for those children who are diagnosed.\textsuperscript{69} In addition, mortality rates remain low.\textsuperscript{60,56,64,65} Findings on chronic respiratory illnesses, compromised immunity, and viral co-infections as risk factors for COVID-19 in children are inconclusive, but comorbidities such as obesity are associated with a higher risk of infection and a more severe clinical course of disease.\textsuperscript{17,75,77,79}

The lower incidence and severity of SARS-CoV-2 infections in children should not allow our focus to shift away from a highly vulnerable population with potential developmental implications. The novelty of COVID-19 has presented many challenges, but there are also unique opportunities to study longitudinally children that have been affected from infancy through childhood and into adulthood. Continued testing and longer-term investigations are warranted to provide data on risk factors for infection and MIS-C, long-term respiratory and developmental outcomes, as well as behavioral and lifestyle influences. Indeed, such knowledge may assist in framing public policy responses that would protect children and mitigate future epidemics.

ACKNOWLEDGMENTS

This study was supported by the National Science Foundation grant (2031761) and Dean’s COVID-19 Rapid Response grant from Tulane University School of Public Health and Tropical Medicine; GP was supported by grant RO1 HL-061007 from the National Heart, Lung and Blood Institutes of Health; SHL was supported by grant P20GM109036 from the National Institute of General Medical Sciences of the National Institutes of Health. The funder/sponsor did not participate in the work.

CONFLICT OF INTERESTS

The authors declare that there are no conflict of interests.
